Abstract

Let P be a simple polygon with n vertices. The geodesic center of P is the point inside P that minimizes the geodesic distance to its farthest neighbor. The best known algorithm to compute the geodesic center of P runs in $O(n \log n)$ time and was presented in 1989. Since then, improving this running time has been a longstanding open problem. In this paper, we show how to compute the geodesic center of P in $O(n \log^* n)$ time.

1 Outline

Let P be a simple polygon with n vertices. Given two points $x, y \in P$, let $\pi(x, y)$ denote shortest path contained in P with endpoints x and y , i.e., $\pi(x, y)$ is the *geodesic path* connecting x with y . Notice that the straight-line segment connecting x with y is contained in P , then $\pi(x, y)$ is a straight-line segment. Otherwise, it is a polygonal chain containing only reflex vertices of P other than its endpoints. The *geodesic distance* between x and y , denoted by $|\pi(x, y)|$, is the euclidean length of the path $\pi(x, y)$, i.e., the sum of the lengths of each segment in this path. Throughout this paper, when referring to the distance between two points in P , we refer to the geodesic distance between them.

Given a point $x \in P$, let $f_P(x)$ (or simply $f(x)$ when the context is clear) denote the vertex of P that is (geodesically) farthest from x (if two or more vertices are at the same distance from x , we choose one of them arbitrarily).

Let $F_P(x) = |\pi(x, f(x))|$, i.e., $F_P(x)$ is the distance from x to its farthest neighbor in P . Another way to think of the function $F_P(x)$ is as the upper envelope of all the (geodesic) distance functions from x to the vertices of P . This is related with the farthest-point geodesic Voronoi diagram of the vertices of P . The *Voronoi cell* of a vertex v of P is the set of points $R(v) = \{x \in P : F_P(x) = |\pi(x, v)|\}$ (including boundary points).

In this paper, we represent the function $F_P(x)$ using a set of constant complexity distance functions defined on triangles contained in P in such a way that the union of these triangles covers P . Moreover, the upper envelope of these functions coincides with $F_P(x)$. Then, we proceed to prune and search for the geodesic center of P by restricting our search to a sub-polygon of P and the triangles that cover this sub-polygon. By pruning a constant fraction of these triangles on each iteration, we are able to obtain a near-linear time algorithm to compute the geodesic center of P . The bottleneck of this algorithm comes from computing the set of triangles that covers P and their respective distance functions.

2 Hourglasses and Funnels

In this section, we introduce the main tools that are going to be used by the algorithm. Some of the result presented in this section have been shown before in different papers. For most of them, we present proof sketches.

2.1 Hourglasses

Given two points x and y on ∂P , let $\partial P(x, y)$ be the polygonal chain that starts at x and follows the boundary of P clockwise until reaching y .

Let $C = (p_0, p_1, \dots, p_k)$ be a polygonal chain contained in ∂P sorted in clockwise order. The *hourglass* of C , denoted by H_C , is the simple polygon contained in P bounded by C , $\pi(p_k, f(p_0))$, $\partial P(f(p_0), f(p_k))$ and $\pi(f(p_k), p_0)$; see Figure 1. We call C and $\partial P(f(a), f(b))$ the *top* and *bottom* chains of H_C , respectively, while $\pi(p_k, f(p_0))$ and $\pi(f(p_k), p_0)$ are referred to as the *walls* of H_C .

We say that the hourglass H_C is *open* if its walls are vertex disjoint. We say C is a *transition chain* if $f(p_0) \neq f(p_k)$ and neither $f(p_0)$ nor $f(p_k)$ are interior vertices of C . In particular, if an edge ab of ∂P is a transition chain, we say that it is a *transition edge*.

► **Lemma 1.** [Rephrase of Lemma 3.1.3 of [2]] *If C is a transition chain of ∂P , then the hourglass H_C is an open hourglass.*

Note that by Lemma 1, the hourglass of each transition chain is open. In the remainder of the paper, all the hourglasses considered are defined by a transition chain, i.e., they are open and their top and bottom chain are edge disjoint.

The following results are similar or have already been proved by Suri [12] and Aronov et al. [2]. We provide a sketch of the proof of some of them for completeness.

The following lemma is depicted in Figure 2 and is a direct consequence of the Ordering Lemma proved by Aronov et al. [2, Corollary 2.7.4].

► **Lemma 2.** *Let C_1, C_2, C_3 be three edge disjoint transition chains of ∂P that appear in this order when traversing clockwise the boundary of P . Then, the bottom chains of H_{C_1}, H_{C_2} and*

■ Figure 2

H_{C_3} are also edge disjoint and appear in this order when traversing clockwise the boundary of P .

► **Lemma 3.** Let C_1, \dots, C_r be a set of edge disjoint transition chains of ∂P that appear in this order when traversing clockwise the boundary of P . Then there is a set of $t = O(1)$ geodesic paths $\gamma_1, \dots, \gamma_t$ such that for each $1 \leq i \leq r$ there exists $1 \leq j \leq t$ such that γ_j separates the top and bottom chains of H_{C_i} .

Proof. Aronov et al. showed that there exist four vertices v_1, \dots, v_4 of P and geodesic paths $\pi(v_1, v_2), \pi(v_2, v_3), \pi(v_3, v_4)$ such that for any point $x \in \partial P$, one of these paths separates x from $f(x)$ [2, Lemma 2.7.6]. Let $\Gamma = \{\pi(v_i, v_j) : 1 \leq i < j \leq 4\}$ and note that v_1, \dots, v_4 split the boundary of P into at most four connected components. If a chain C_i is completely contained in one of this components, then one path of Γ separates the top and bottom chain of H_{C_i} . Otherwise, some vertex v_j is an interior vertex of C_i . However, because the chains C_1, \dots, C_r are edge disjoint, there are at most four chains in this situation. For each chain C_i containing a vertex v_j , we add the geodesic path connecting the endpoints of C_i to Γ . Therefore, Γ consists of $O(1)$ geodesic paths and each hourglass H_{C_i} has its top and bottom chain separated by some path of Γ . ◀

A *chord* of P is an edge joining two non-adjacent vertices a and b of P such that $ab \subseteq P$. Therefore, a chord splits P into two sub-polygons.

► **Lemma 4.** [Rephrase of Lemma 3.4.3 of [2]] Let C_1, \dots, C_r be a set of edge disjoint transition chains of ∂P that appear in this order when traversing clockwise the boundary of P . Then each chord of P appears in $O(1)$ hourglasses among H_{C_1}, \dots, H_{C_r} .

Proof. Assume for a contradiction that there is a chord st that appears in three hourglasses H_{C_i}, H_{C_j} and H_{C_k} such that $1 \leq i < j < k \leq r$. Note that chords can only appear on the walls of these hourglasses. Because the hourglasses are open, st must be an edge on exactly one wall of each of these hourglasses.

Assume that s is visited before t when going from the top to the bottom chain along these walls. Let $\pi(s_i, t_i)$ be the wall of S_i that contains st such that s_i and t_i lie in the top and bottom chains of H_{C_i} , respectively. Define $\pi(s_k, t_k)$ analogously.

Because C_j lies in between C_i and C_k , Lemma 2 implies that the bottom chain of C_j appears between the bottom chains of C_i and C_k . Therefore, C_j lies between s_i and s_k and the bottom chain of H_{C_j} lies between t_i and t_k . That is, for each $x \in C_j$ and each y in the bottom chain of H_{C_j} , the geodesic path $\pi(x, y)$ is “sandwiched” by the paths $\pi(s_i, t_i)$ and $\pi(s_k, t_k)$. Thus, $\pi(x, y)$ contains st . However, this implies that the hourglass H_{C_j} is not open—a contradiction that comes from assuming that st lies in the wall of three open hourglasses, when this wall is traversed from the top chain to the bottom chain. Analogous arguments can be used to bound the total number of walls that contain the edge st (when traversed in any direction) to $O(1)$. ◀

► **Lemma 5.** [Rephrase of Lemma 4 of [12]] *Let C be a transition chain and let B_C be the bottom chain of H_C . Let x, y be two vertices such that $\pi(x, y)$ separates C from B_C . If T_x and T_y are the shortest path trees of x and y in P , then for each $u \in C$ and each $v \in B_C$, all edges of $\pi(u, v)$, except perhaps one, belong to $T_x \cup T_y$.*

► **Lemma 6.** *Let P be a simple polygon with n vertices. Given k disjoint transition chains C_1, \dots, C_k of ∂P , it holds that*

$$\sum_{i=1}^k |H_{C_i}| = O(n).$$

Proof. Because the given transition chains are disjoint, the bottom chains of their respective hourglasses are also disjoint by Lemma 2. Therefore, the sum of the complexities of all the top and bottom chains of these hourglasses amounts to $O(n)$. To bound the complexity of their walls, note that Lemma 4 implies that no chord is used more than a constant number of times. Thus, if the total number of chords used by all these hourglasses is $O(n)$, then our result follows.

To prove this, we use Lemma 3 to construct $O(1)$ *split chains* $\gamma_1, \dots, \gamma_t$ such that for each $1 \leq i \leq k$, there is a split chain γ_j that separates the top and bottom chain of H_{C_i} . For each $1 \leq j \leq t$, let

$$\mathcal{H}^j = \{H_{C_i} : \text{the top and bottom chain of } H_{C_i} \text{ are separated by } \gamma_j\}.$$

Since the complexity of the shortest path trees of the endpoints of γ_j is $O(n)$, and from the fact that the chains C_1, \dots, C_k are disjoint, Lemma 5 implies that the total number of edges in all the hourglasses of \mathcal{H}^j is $O(n)$. Moreover, because each of these edges appears in $O(1)$ hourglasses among C_1, \dots, C_k , we conclude that

$$\sum_{H \in \mathcal{H}^j} |H| = O(n).$$

Since we have only $O(1)$ split chains, our result follows. ◀

2.2 Funnels

Let $C = (p_0, \dots, p_k)$ be a chain of the boundary of P and let v be a vertex of P not in C . The *funnel* of v to C , denoted by $S_v(C)$, is the simple polygon bounded by C , $\pi(p_k, v)$ and $\pi(v, p_0)$; see Figure 2. Note that the paths $\pi(v, p_k)$ and $\pi(v, p_0)$ may coincide for a while before splitting into disjoint chains. See Lee and Preparata [6] or Guibas et al. [3] for more details on funnels.

A subset $R \subset P$ is *geodesically convex* if for every $x, y \in R$, the path $\pi(x, y)$ is contained in R . This funnel $S_v(C)$ is also known as the geodesic convex hull of C and v , i.e., the minimum geodesically convex set that contains v and C .

Given two points $x, y \in P$, the (geodesic) *bisector* of x and y is the set of points contained in P that are equidistant from x and y . This bisector is a curve, contained in P , that consists of circular arcs and hyperbolic arcs. Moreover, this curve intersects ∂P only at its endpoints [1, Lemma 3.22].

► **Lemma 7.** *Let v be a vertex of P and let C be a transition chain such that C contains $R(v) \cap \partial P$ and v is not contained in C . Then, $R(v)$ is contained in the funnel $S_v(C)$*

Proof. Let a and b be the endpoints of C and assume that $a, b, f(a)$ and $f(b)$ appear in this order in a clockwise traversal of ∂P . Because $R(v) \cap \partial P \subset C$, we know that v lies between $f(a)$ and $f(b)$.

Let α (resp. β) be the bisector of v and $f(a)$ (resp. $f(b)$). Let h_a (resp. h_b) be the set of points of P that are farther from v than from $f(a)$ (resp. $f(b)$). Note that α is the boundary of h_a while β bounds h_b .

By definition, we know that $R(v) \subseteq h_a \cap h_b$. Therefore, it suffices to show that $h_a \cap h_b \subset S_v(C)$. Assume for a contradiction that there is a point of $h_a \cap h_b$ lying outside of $S_v(C)$. By continuity, there is a point w lying in the intersection of their boundaries. Without loss of generality, assume that w lies in $\beta \cap \pi(v, b)$, the case where w lies in $\alpha \cap \pi(v, a)$ is analogous.

Since $w \in \beta$, we know that $|\pi(w, v)| = |\pi(w, f(b))|$. By the triangle inequality and since w cannot be a vertex of P as w intersects ∂P only at its endpoints, we get that

$$|\pi(b, f(b))| < |\pi(b, w)| + |\pi(w, f(b))| = |\pi(b, w)| + |\pi(w, v)| = |\pi(b, v)|.$$

Which implies that b is farther from v than from $f(b)$ —a contradiction that comes from assuming that $h_a \cap h_b$ is not contained in $S_v(C)$. ◀

3 Decomposing the boundary

Using a result from Hershberger and Suri [5], in $O(n)$ time we can compute the farthest neighbor of each vertex of P . We then mark the vertices of P that are farthest neighbors of at least one vertex of P . Let M denote the set of marked vertices of P which can be computed in $O(n)$ time. In other words, M contains all vertices of P whose Voronoi cell contains at least one vertex of P .

Given a vertex v of P , the vertices of P that are farthest from v than from any other vertex appear contiguously along ∂P [2]. Therefore, after computing all this farthest neighbors, we effectively split the boundary into subchains, each associated with a different vertex of M ; see Figure 3.

Let a and b be the endpoints of a transition edge of ∂P and assume that a appears before b in the clockwise order along ∂P . Recall that we have computed $f(a)$ and $f(b)$ in the previous step and note that $f(a)$ appears also before $f(b)$ along this clockwise order. For every vertex v that lies between $f(a)$ and $f(b)$ in the bottom chain of H_{ab} , we know that there is no vertex u of P such that $f(u) = v$. As proved by Aronov et al. [2, Corollary 2.7.4], we know that if there is a point x on ∂P such that $v = f(x)$, then x has to lie on the open segment (a, b) . In other words, the Voronoi cell $R(v)$ restricted to ∂P is contained in (a, b) .

■ Figure 3

4 Building hourglasses

Let E be the set of transition edges of ∂P . Given a transition edge $ab \in E$, we say that H_{ab} is a *transition hourglass*. In order to construct the triangle cover of P , we need to construct the transition hourglass of each transition edge of E .

By Lemma 6, we know that $\sum_{ab \in E} |H_{ab}| = O(n)$. Therefore, an output sensitive algorithm would suffice for this task. However, we have no knowledge of the existence of such an algorithm. The algorithm proposed in this section achieves this task at the expense of adding an $O(\log^* n)$ factor to the running time.

To construct these transition hourglasses, we use the shortest-path data structure of Guibas and Hershberger which can be constructed in $O(n)$ time [4]. Given two points $p, q \in P$, this structure allows us to compute the path $\pi(p, q)$ in $O(\log n + t)$ time, where t is the number of vertices in $\pi(p, q)$. While constructing these paths using this structure can take $\Omega(n \log n)$ time, we overcome this issue by splitting the problem into subproblems whose total complexity amounts to $O(n)$.

We start by choosing $k = n/\log n$ vertices along ∂P , say v_0, v_1, \dots, v_{k-1} , chosen by walking along ∂P in clockwise order and choosing a vertex each time we skip $\log n$ transition edges. In other words, we decompose the boundary of P into k transition chains C_0, \dots, C_{k-1} , each of length at most $\log n$, such that v_i and v_{i+1} are the endpoints of C_i (index taken modulo k).

We now compute the k transition hourglasses of these transition chains. To this end, for each $0 \leq i \leq k-1$, we compute the path $\pi(v_i, f(v_{i+1}))$ and the path $\pi(v_{i+1}, f(v_i))$. These two paths together with the chain between v_i and v_{i+1} and the chain between $f(v_{i+1})$ and $f(v_i)$ form a hourglass. In this way, we obtain $k = n/\log n$ hourglasses H_0, \dots, H_{k-1} such that for each $1 \leq i \leq k-1$, the top chain of H_i has at most $\log n$ vertices. Since $\sum_{ab \in E} |H_{ab}| = O(n)$ and from the fact that the boundary of each hourglass is contained in the boundary of a hourglass of an edge of E , we conclude that $\sum_{i=0}^{k-1} |H_{k-1}| = O(n)$. Since $k = n/\log n$, the $O(\log n)$ overhead of the shortest-path queries amounts only to $O(n)$. Thus, we can compute these k hourglasses in $O(n)$ time [4].

We now look at each H_i independently and recursively split H_i into smaller hourglasses as follows. Let E_i be the number of transition edges in the top chain of H_i and let $m_i = |H_i|$. We start by computing the shortest-path data structure for H_i in $O(m_i)$ time. Recall that

$|E_i| \leq \log n$ by the way we constructed each H_i . Note that the transition hourglass of each transition edge of E_i is contained in H_i . Because each of these hourglasses is open, we know that $\sum_{ab \in E_i} |H_{ab}| = O(m_i)$ by Lemma 6.

Two cases arise: if (1) $|E_i| \leq m_i / \log m_i$, then computing the $|E_i|$ transition hourglasses defined by the transition edges of E_i takes $O(|E_i| \log m_i + \sum_{ab \in E_i} |H_{ab}|) = O(m_i)$ time. If we are in this case, then we compute each of the transition hourglasses and finish the recursion. Otherwise, we know that (2) $m_i / \log m_i \leq |E_i|$, and because $|E_i| \leq \log n$, we conclude that $m_i \leq \log^2 n$. Therefore, by splitting the top chain of H_i into $m_i / \log m_i$ chains of length at most $\log m_i$, and repeating the process described above, we can construct at most $m_i / \log m_i$ hourglasses, whose upper chains have at most $\log m_i = O(\log \log n)$ vertices. Because these $m_i / \log m_i$ hourglasses are contained in H_i , their total complexity amounts to $O(m_i)$ by Lemma 6. Using the shortest-path data structure of H_i , we can compute these $m_i \log m_i$ hourglasses in $O(m_i)$ time. Since $\sum_{i=0}^{k-1} m_i = O(n)$, the total complexity of this step in all hourglasses is at most $O(n)$.

Because the length of the top chain of each hourglasses decreases by taking the logarithmic function, after $O(\log^* n)$ rounds we will be able to compute all the hourglasses for the edges of E . We obtain the following result.

► **Lemma 8.** *If E is the set of transition edges of P , then we can construct the transition hourglass of each edge E in total $O(n \log^* n)$ time.*

5 Covering the polygon with apexed triangles

An *apexed triangle* $\triangle = (a, b, c)$ with *apex* a is a triangle contained in P with an associated distance function $g_\triangle(x)$, called the *apex function* of \triangle , such that (1) a is a vertex of P , (2) b and c are points on the boundary of P , and (3) there is a vertex w of P , called the *definer* of \triangle , such that

$$g_\triangle(x) = \begin{cases} -\infty & \text{if } x \notin \triangle \\ |xa| + |\pi(a, w)| = |\pi(x, w)| & \text{if } x \in \triangle \end{cases}$$

In this section, we show how to find a set of $O(n)$ apexed triangles of P such that the upper envelope of their apex functions coincides with $F_P(x)$. To this end, we first decompose the transition hourglasses into apex triangles that encode all the geodesic distance information inside them. Then, for each marked vertex $v \in M$, we construct a funnel that contains the Voronoi cell of v . We then decompose this funnel into apex triangles that encode the distance from v .

5.1 Inside the transition hourglass

Let ab be a transition edge of P such that b is the clockwise neighbor of a along ∂P . Let B_{ab} denote the bottom chain of H_{ab} . As noticed above, a point on ∂P can be farthest from a vertex in B_{ab} only if it lies in the open segment ab . Formally, if v is a vertex of B_{ab} such that $R(v) \neq \emptyset$, then $R(v) \cap \partial P \subset ab$. We claim that not only this Voronoi cell is inside H_{ab} when restricted to the boundary of P , but that $R(v) \subset H_{ab}$.

► **Lemma 9.** *Let v be a vertex of B_{ab} . If $R(v) \neq \emptyset$, then $R(v) \subset H_{ab}$.*

Proof. Because $R(v) \cap \partial P \subset ab$, by Lemma 7, we know that $R(v) \subset S_v(ab)$. Because H_{ab} is geodesically convex, we conclude that $R(v) \subset S_v(ab) \subset H_{ab}$. ◀

■ Figure 4

Our objective is to compute $O(|H_{ab}|)$ apexed triangles that cover H_{ab} , each with its distance function, such that the upper envelope of these apex functions coincides with $F_P(x)$ restricted to H_{ab} where it “matters”.

A similar approach was already carried on by Pollack et al. in [11, Section 3]. They show, given a segment contained in the interior of P , how to compute a linear number of apexed triangles such that $F_P(x)$ coincides with the upper envelope of the corresponding apex functions in the given segment.

While the construction we follow is analogous, we use it in the transition hourglass H_{ab} instead of the full polygon P . Therefore, we have to specify what is the relation between the upper envelope of the computed functions and $F_P(x)$. We will show that the upper envelope of the apex functions computed in H_{ab} coincides with $F_P(x)$ inside the Voronoi cell $R(v)$ of every vertex $v \in B_{ab}$.

Let T_a and T_b be the shortest path trees in H_{ab} from a and b , respectively. Assume that T_a and T_b are rooted at a and b , respectively. We can compute these trees in $O(|H_{ab}|)$ time [3]. For each vertex v between $f(a)$ and $f(b)$, let v_a and v_b be the neighbors of v in the paths $\pi(v, a)$ and $\pi(v, b)$, respectively. We say that a vertex v is *visible* from ab if $v_a \neq v_b$. Note that if a vertex is visible, then the extension of these segments must intersect the top segment ab . Therefore, for each visible vertex v , we obtain a triangle Δ_v as shown in Figure 4.

We further split Δ_v into a series of triangles with apex at v as follows: Let u be a child of v in either T_a or T_b . As noted by Pollack et al., v can be of three types, either (1) u is not visible from ab (and is hence a child of v in both T_a and T_b); or (2) u is visible from ab , is a child of v only in T_b , and v_bvu is a left turn; or (3) u is visible from ab , is a child of v only in T_a , and v_avu is a right turn.

Let u_1, \dots, u_{k-1} be the children of v of type (2) sorted in clockwise order around v . Let $c(v)$ be the maximum distance from v to any invisible vertex in the subtrees of T_a and T_b rooted at v ; if no such vertex exists, then $c(v) = 0$. Define a function $d_l(v)$ on each vertex v of H_{ab} in a recursive fashion as follows: If v is invisible from ab , then $d_l(v) = c(v)$. Otherwise, let $d_l(v)$ be the maximum of $c(v)$ and $\max\{d_l(u_i) + |u_iv| : u_i \text{ is a child of } v \text{ of type (2)}\}$. Similarly we define a symmetric function $d_r(v)$ using the children of type (3) of v .

For each $1 \leq i \leq k-1$, extend the segment u_iv past v until it intersects ab at a point s_i . Let s_0 and s_k be the intersections of the extensions of vv_a and vv_b with the segment ab .

We define then k triangles contained in Δ_v as follows. For each $0 \leq i \leq k-1$, consider the triangle $\Delta(s_i, v, s_{i+1})$ whose associated apexed (left) function is

$$f_i(x) = |xv| + \max_{j>i} \{c(v), |vu_j| + d_l(u_j)\}.$$

In a symmetric manner, we define a set of apexed triangles induced by the type (3) children of v and their respective apexed (right) functions.

Let g_1, \dots, g_r and $\Delta_1, \dots, \Delta_r$ respectively be an enumeration of all the generated apex functions and triangles such that g_i is defined in the triangle Δ_i . Because each function is determined uniquely by a pair of adjacent vertices in T_a or in T_b , and since these trees have $O(|H_{ab}|)$ vertices, we conclude that $r = O(|H_{ab}|)$.

Note that for each $1 \leq i \leq r$, the triangle Δ_i has two vertices on the segment ab and a third vertex, say a_i , called its *apex* such that for each $x \in \Delta_i$, $g_i(x) = |\pi(x, w_i)|$ for some vertex w_i of H_{ab} . We refer to w_i as the *definer* of Δ_i . Intuitively, Δ_i defines a portion of the geodesic distance function from w_i in a constant complexity region.

► **Lemma 10.** *Given a transition edge ab of P , we can compute $O(|H_{ab}|)$ apexed triangles and their respective apex functions in $O(|H_{ab}|)$ time. Moreover, for any point $p \in P$ such that $f(p) \in B_{ab}$, there is a computed apexed triangle Δ_i with apex function g_i and definer equal to $f(p)$ such that*

1. $p \in \Delta_i$ and
2. $g_i(p) = F_P(p)$.

Proof. Because $p \in R(f(p))$, Lemma 9 implies that $p \in H_{ab}$. Consider the path $\pi(p, f(p))$ and let v be the neighbor of p along this path. Note that by construction, there is a triangle Δ_i apexed at v_i with definer w_i that contains p . Recall that by construction, the apex function $g_i(x)$ of Δ_i encodes the geodesic distance from x to w_i . Because $F_P(x)$ is the upper envelope of all the geodesic functions, we know that $g_i(p) \leq F_P(p)$.

To prove the other inequality, note that if $v_i = f(p)$, then trivially $g_i(p) = |pv_i| + |\pi(v_i, w_i)| \geq |pv_i| = |\pi(p, f(p))| = F_P(p)$. Otherwise, let z be the next vertex after v_i in the path $\pi(p, f(p))$. Three cases arise:

(a) If z is invisible from ab , then so is $f(p)$ and hence,

$$|\pi(p, f(p))| = |pv_i| + |\pi(v_i, f(p))| \leq |pv_i| + c(v_i) \leq g_i(p).$$

(b) If z is a child of type (2), then z plays the role of some child u_j of v_i in the notation used during the construction. In this case:

$$|\pi(p, f(p))| = |pv_i| + |v_i z| + |\pi(z, f(p))| \leq |pv_i| + |v_i u_j| + d_l(u_j) \leq g_i(p).$$

(c) If z is a child of type (3), then an analogous arguments hold using the (right) distance d_r .

Therefore, regardless of the case $F_P(p) = |\pi(p, f(p))| \leq g_i(p)$. ◀

In other words, Lemma 10 says that by considering the apex functions we computed, we do not lose any information inside any region $R(v)$ of any vertex $v \in B_{ab}$.

Following the same intuition, in the next section we construct apexed triangles and their apex functions encoding the distance from the vertices of M .

5.2 Inside the funnels of marked vertices

Recall that for each marked vertex $v \in M$, we know at least of one vertex on ∂P such that v is its farthest neighbor. Let u_1, \dots, u_{k-1} be the set of vertices of P such that $v = f(u_i)$ and assume that they appear in this order when traversing ∂P clockwise. Let u_0 and u_k be the neighbors of u_1 and u_{k-1} other than u_2 and u_{k-2} , respectively. Note that both u_0u_1 and $u_{k-1}u_k$ are transition edges of P . Thus, we can assume that their transition hourglasses have been computed.

Let $C_v = (u_0, \dots, u_k)$ and consider the funnel $S_v(C_v)$. We call C_v the *main chain* of $S_v(C_v)$ while $\pi(u_k, v)$ and $\pi(v, u_1)$ are referred to as the *walls* of the funnel. Because $v = f(u_1) = f(u_{k-1})$, we know that v is a vertex of both $H_{u_0u_1}$ and $H_{u_{k-1}u_k}$. Thus, since $\pi(v, u_1) \subset H_{u_0u_1}$ while $\pi(v, u_k) \subset H_{u_{k-1}u_k}$, we can compute both $\pi(v, u_1)$ and $\pi(v, u_k)$ in $O(|H_{u_0u_1}| + |H_{u_{k-1}u_k}|)$ time. Consequently, the funnel $S_v(C_v)$ can be constructed in $O(k + |H_{u_0u_1}| + |H_{u_{k-1}u_k}|)$.

Because a vertex on ∂P has a unique farthest neighbor by our general position assumption, and since the total sum of the complexities of the transition hourglasses is $O(n)$ by Lemma 6, we can compute the funnel of each vertex of M in total $O(n)$ time.

Since the complexity of the walls of these funnels is bounded by the complexity of the transition hourglasses used to compute them, we get that

$$\sum_{v \in M} |S_v(C_v)| = O\left(n + \sum_{ab \in E} |H_{ab}|\right) = O(n).$$

► **Lemma 11.** *Let x be a point in P . If $v = f(x)$, then $x \in S_v(C_v)$.*

Proof. Because $f(u_0) \neq f(u_k)$, we know that C_v is a transition chain. Moreover, C_v contains $R(v) \cap \partial P$ by definition. Therefore, by Lemma 7, we know that $R(v) \subset S_v(C_v)$. Since $v = f(x)$, we know that $x \in R(v)$ and hence that $x \in S_v(C_v)$. ◀

Given a funnel $S_v(C_v)$, we would like to split it into $O(|S_v(C_v)|)$ apexed triangles that encode the distance function from v . To this end, we compute the shortest path tree T_v of v in $S_v(C_v)$ in $O(|S_v(C_v)|)$ time [4]. We consider the tree T_v to be rooted at v and assume that for each node u of this tree we have stored the geodesic distance $|\pi(u, v)|$.

Let w_1 be the first leaf of T_v found when walking from v around T_v in clockwise order as in an Eulerian tour. Continue this Eulerian tour from w_1 and let w_2 and w_3 be the next two vertices visited. Two cases arise:

Case 1. If w_1, w_2, w_3 makes a left turn, then let s be the first point of the boundary of $S_v(C_v)$ hit by the ray shooting from w_3 in the direction opposite to w_2 (s could be equal to w_3 if w_3 already lies on the boundary). We claim that s and w_1 lie on the same edge of the boundary of $S_v(C_v)$. Otherwise, there would be a vertex u visible from w_2 inside the wedge with apex w_2 spanned by w_1 and w_3 . Note that the first edge of the path $\pi(u, v)$ is the edge uw_2 . Therefore, uw_2 belongs to the shortest path T_v contradicting the Eulerian order in which the vertices of this tree are visited as u should be visited before w_3 . Thus, s and w_1 lie on the same edge and s can be computed in $O(1)$ time. We then construct an apexed triangle $\triangle(w_1, w_2, s)$ apexed at w_2 with apex function $g(x) = |xw_2| + |\pi(w_2, v)|$. We now modify the tree T_v by removing the edge w_1w_2 and adding the edge w_3s (no edge is added if $w_3 = s$); see Figure 5 for an illustration.

Case 2. If w_1, w_2, w_3 makes a right turn, then let s be the first point hit by the ray apexed at w_2 that shoots in the direction opposite to w_3 . By the same argument as above, we can show that w_1 and s lie on the same edge of the boundary of $S_v(C_v)$. Therefore, we

■ Figure 5

can compute s in $O(1)$ time. At this point, we construct the apexed triangle $\Delta(w_1, w_2, s)$ apexed at w_2 with apex function $g(x) = |xw_2| + |\pi(w_2, v)|$. We now modify the tree T_v by removing the edge w_1w_2 and replacing the edge w_3w_2 by the edge w_3s ; see Figure 5.

► **Lemma 12.** *The above procedure runs in $O(|S_v(C_v)|)$ time and computes $O(|S_v(C_v)|)$ interior disjoint apexed triangles such that their union covers $S_v(C_v)$. Moreover, for each point $x \in S_v(C_v)$, there is an apexed triangle Δ with apex function $g(x)$ such that (1) $x \in \Delta$ and (2) $g(x) = |\pi(x, v)|$.*

Proof. The above procedure splits $S_v(C_v)$ into apexed triangles, such that the apex function in each of them is defined as the geodesic distance to v . Since the path towards v of every point in these triangles has to go through their apex, we obtain properties (1) and (2).

To bound the running time and complexity we proceed as follows. We can compute the shortest-path tree T_v from v in $O(|S_v(C_v)|)$ time [4]. Note that processing either Case 1 or 2 of the algorithm takes constant time. Therefore, we are only interested in the number of times these steps are performed. Note that we are removing a leaf of the tree in each iteration. In Case 2, the number of leaves strictly decreases, while in case one a new leaf is added if $s \neq w_3$. However, the number of leaves that can be added is at most the number of edges of T_v . Note that the edges added by either Case 1 or 2 are chords of the polygon and hence cannot generate further leaves. Because $|T_v| = O(|S_v(C_v)|)$, we conclude that either Case 1 or 2 is only executed $O(|S_v(C_v)|)$ times yielding the bound in the number of produced apexed triangles and in the running time. ◀

6 Prune and search

In this section, we describe a procedure that finds either the geodesic center of P , or a convex trapezoid that contains the geodesic center. The idea of the proof is to consider the chords of the apexed triangles computed in previous sections and use a cutting of them that splits P into $O(1)$ cells. Then, we test on which cell the geodesic center lies and recurse on that cell as a new subproblem having smaller complexity. To decrease the complexity of the problem, we consider only the apexed triangles intersecting this cell in the next iteration. Using the properties of the cutting, we are able to prove that the size of the subproblem decreases by a constant fraction which leads to a linear running time. This algorithm has however two stopping conditions, one is to reach a subproblem of constant size, and a second one is to find a convex trapezoid containing the geodesic center. In the latter case, we are not able to proceed with the prune and search. Nevertheless, by restricting the search space to a convex object, we are able to perform standard optimization techniques to find the geodesic center.

Let τ be the set all apexed triangles computed in previous sections.

► **Lemma 13.** *The set τ consists of $O(n)$ apexed triangles.*

Proof. To bound the complexity of τ , recall that E denotes the set of transition edges of P . Because $\sum_{ab \in E} H_{ab} = O(n)$ by Lemma 6 and since there are $O(|H_{ab}|)$ apexed triangles in each transition hourglass H_{ab} , we conclude that there $O(n)$ apexed triangles constructed using Lemma 6.

Furthermore, we know that $\sum_{v \in M} |S_v(C_v)| = O(n)$. Because each funnel $S_v(C_v)$ is subdivided into $O(|S_v(C_v)|)$ apexed triangles by Lemma 12, we conclude that at most $O(n)$ apexed triangles are constructed inside funnels of marked vertices. Consequently $|\tau| = O(n)$. ◀

Let $\phi(x)$ be the upper envelope of the apex functions of every triangle in τ , i.e.,

$$\phi(x) = \max\{g(x) : g(x) \text{ is the apex function of some apexed triangle of } \tau\}.$$

The following result shows that the $O(n)$ apexed triangle of τ not only cover P , but their apex functions suffice to reconstruct the function $F_P(x)$.

► **Lemma 14.** *The functions $\phi(x)$ and $F_P(x)$ coincide in the domain of points of P , i.e., for each $p \in P$, $\phi(p) = F_P(p)$.*

Proof. Let p be a point in P , we want to prove that $\phi(p) = F_P(p)$. Two cases arise: **Case 1.** If $f(p)$ is a marked vertex, then Lemma 11 implies that $p \in S_{f(p)}(C_{f(p)})$. Therefore by Lemma 12 there is an apexed triangle Δ with apex function $g(x)$ such that $p \in \Delta$ and $g(p) = |\pi(p, f(p))| = F_P(p)$.

Case 2. If $f(p)$ is not marked, then it belongs to the bottom chain of some transition hourglass. In this case by Lemma 10 there is an apexed triangle Δ with apex function $g(x)$ such that $p \in \Delta$ and $g(p) = F_P(p)$.

Regardless of the case, there is an apexed triangle Δ that contains p such that its apex function $g(p) = F_P(p)$. Since each apex function represent the geodesic distance from some vertex of P , we know that $\phi(p) \leq F_P(p)$. Moreover, since $g(x)$ is an apex function, we know that $g(p) \leq \phi(p)$. Because $g(p) = F_P(p)$ and since $g(p) \leq \phi(p) \leq F_P(p)$, we conclude that $\phi(p) = F_P(p)$ proving our claim. ◀

A P -chain is a polygonal chain contained in the boundary of P . A P -cell is a simple polygon contained in P bounded by a P -chain and a polygonal chain of length at most four

■ Figure 6

contained in the interior of P that connects the endpoints of this P -chain. Moreover, a P -cell contains the geodesic center of P . The recursive algorithm described in this section takes as input a P -cell (originally the whole polygon P) and the set of apexed triangles of τ that intersect this P -cell, and produces then a new P -cell of smaller complexity.

Given a P -cell R , let τ_R be the set of apexed triangles of τ that intersect R . Let R be a P -cell and assume that the set τ_R has been computed. Let $m = \max\{|R|, |\tau_R|\}$.

Note that each triangle of τ_R consists of at least one chord of R . Let C be the set containing all chords that bound a triangle of τ_R . A *half-chord* of R is either of the simple polygons in which a chord of R splits this polygon. An *R -trapezoid* is the simple polygon obtained as the intersection of at most four half-chords. Consider a set Q of all open R -trapezoids. For each $q \in Q$, let $C_q = \{c \in C : c \cap q \neq \emptyset\}$ be the set of chords of C induced by q . Finally, let $Q_C = \{C_q : q \in Q\}$ be the family of subsets of C induced by Q .

Consider the range space defined by C and Q_C . Let $\varepsilon > 0$. Because the VC-dimension of this range space is finite, we can compute an ε -net N of (C, Q_C) of size $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}) = O(1)$ such that for any R -trapezoid q , if q intersects no chord of N , then q intersects at most $\varepsilon|C|$ chords of C . Note that N can be computed in $O(n)$ time [8].

Since $|N| = O(1)$, we can compute all the intersections in this arrangement in $O(1)$ time. Moreover, by looking at the endpoints of all the chords in N , we can implicitly compute the partition of R into $O(1)$ sub-polygons that this arrangement induces. While each cell of the arrangement is bounded by a constant number of chords from N and a connected chain of the boundary of R , it may not be an R -trapezoid. Therefore, we split them into R -trapezoids by doing a vertical ray-shooting up and down from every vertex of the arrangement; see Figure 6. Since only $O(1)$ ray-shootings are performed, this can be done in additional $O(m)$ time by walking the boundary of the polygon R .

We want to decide now which R -trapezoid contains the geodesic center of P . To this end, for each edge of an R -trapezoid, we can extend it to a chord C by doing two ray-shooting queries in $O(m)$ time. Then, we can use the second part of the relative center algorithm introduced by Pollack et al. [11, Section 3] to find the point on C that minimizes $F_P(x)$ (during the first part of their algorithm they compute the equivalent of apex functions restricted to C). This algorithm is an extension of the linear programming technique introduced by Megiddo [9]. The only requirement of this technique is that the function $F_P(x)$ coincides with the upper envelope of the apex functions when restricted to C .

Recall that τ_R consists of all the apexed triangles that intersect R . Thus, we have all the apexed triangles that intersect C . Consequently, Lemmas 10 and 12 imply that the upper envelope of the apex functions coincides with $F_P(x)$ when restricted to C . Let $p \in C$ be

the point that archives the minimum of $F_P(x)$ (note that p may be an endpoint of C). We want to decide now on which side of C lies the optimum of $F_P(x)$, i.e., the geodesic center of x . To this end, we consider the apexed triangles whose apex functions define the value of $F_P(x)$ at p . They can be found in $O(m)$ time by looking at all the apexed triangles of τ_R that contain p . We then consider the definers of these apexed triangles. By looking at their distance function to p , which is encoded by the apex functions, we can decide locally on which side of C the function decreases and determine the side that contains the optimum of $F_P(x)$.

Because the algorithm described by Pollack et al. [11, Section 3] runs in linear time on the number of functions defined on C , we can decide in total $O(m)$ time on which side of C the geodesic center of P lies.

Because our decomposition into R -trapezoids has constant complexity, we need to perform this test only $O(1)$ times before determining the R -trapezoid q^* that contains the geodesic center of P . Since N is a ε -net, we know that at most $\varepsilon|C|$ chords of C intersect q^* .

If q^* is contained in the interior of R , then q^* is convex. In this case, we have found a convex trapezoid that contains the solution and this algorithm finishes. Otherwise, q^* is a P -cell bounded by at most three segments, say α, β and γ , and some P -chain R_{q^*} ; see Figure 6. In order to proceed with the algorithm on q^* recursively, we need to compute the set τ_{q^*} of at most $\varepsilon|C|$ apexed triangles of τ_R that intersect q^* . We proceed as follows.

For each apexed triangle $\triangle \in \tau_R$, we consider the index of its endpoints and test in $O(1)$ time if any of them lies on the P -chain R_{q^*} . If they do, then they intersect q^* . Otherwise, we know that this triangle has no endpoint in R_{q^*} and could only intersect q^* if one of its edges intersects either α, β or γ . Since this can be tested in $O(1)$ time, we conclude that the at most $\varepsilon|C|$ triangles of τ_R that intersect q^* can be found in $O(m)$ time. Because $|C| \leq 2m$, we guarantee that at most $2\varepsilon m$ apexed triangles intersect q^* . Moreover, because each vertex of q^* is in at least one apexed triangle of τ_R and from the fact that each apexed triangle covers at most three vertices, we conclude that q^* consists of at most $6\varepsilon m$. Thus, by choosing $\varepsilon = 1/12$, we guarantee that both the size of the P -cell q^* and the number of apexed triangles in τ_{q^*} are at most $m/2$.

By recursing on q^* , we guarantee that after $O(\log m)$ iterations, we will find either a convex trapezoid contained in R that contains the center, or we reduce the size of τ_R to a constant in which case the optimum of $F_P(x)$ can be found using an exhaustive search in $O(1)$ time. Since we halve the size of the P -cell and the number of apexed triangles in each iteration, the total running time of this algorithm is given by the recurrence $T(m) = T(m/2) + O(m)$ which solves to $T(m) = O(m)$. Because $|\tau| = O(n)$ by Lemma 13, the total running time of this algorithm on P is $O(n)$.

► **Lemma 15.** *In $O(n)$ time we can find either the geodesic center of P or a convex trapezoid containing this geodesic center.*

7 Solving the problem restricted to a convex trapezoid

In the previous section we show how to find either the geodesic center of P , or a convex trapezoid q^* contained in P that contains this center. Recall that $\phi(x)$ denotes the upper envelope of the apex functions of every triangle in τ . The important thing to notice is that, as in the case of chords, the function $\phi(x)$ restricted to q^* is a convex function, which allows us to do prune and search using cuttings.

Let $\Delta_1, \Delta_2, \dots, \Delta_m$ be the set of $m = O(n)$ apexed triangles of τ that intersect q^* . Let $g_i(x) = |xa_i| + \kappa_i$ be the apex function of Δ_i , where a_i and w_i are the apex and the definer

of Δ_i , respectively, and $\kappa_i = |\pi(a_i, w_i)|$ is a constant.

Recall that the geodesic center of P is the point in P that minimizes the function $F_P(x)$. By Lemma 14, $\phi(x) = F_P(x)$. Therefore, the problem of finding the point that minimizes $F_P(x)$ can be reduced to the following optimization problem in \mathbb{R}^3 :

(P1). Find a point $(x, r) \in \mathbb{R}^3$ minimizing r subject to $x \in q^*$ and

$$g_i(x) = |xa_i| + \kappa_i \leq r, \text{ if } x \in \Delta_i \text{ for } 1 \leq i \leq m.$$

Thus, we need only to find the solution to (P1) to find the geodesic center of P . A similar optimization was studied by Megiddo in [10]. The main difference being that we have apex functions, defined only in their corresponding apexed triangles, instead of functions defined in the entire plane.

We use some remarks described by Megiddo in order to simplify the description of (P1). To simplify the formulas, we square the equations:

$$g_i(x) = \|x\|^2 + 2x \cdot a_i + \|a_i\|^2 = |xa_i|^2 \leq (r - \kappa_i)^2 = r^2 - 2r\kappa_i + \kappa_i^2$$

And finally for each $1 \leq i \leq m$, we define the function $h_i(x, r)$ as follows:

$$h_i(x, r) = \|x\|^2 + 2x \cdot a_i + \|a_i\|^2 - r^2 + 2r\kappa_i - \kappa_i^2 \leq 0$$

Therefore, our optimization problem can be reformulated as:

(P2). Find a point $(x, r) \in \mathbb{R}^3$ such that r is minimized subject to $x \in q^*$ and

$$h_i(x, r) \leq 0, \text{ if } x \in \Delta_i \text{ for } 1 \leq i \leq m.$$

Although the functions $h_i(x, r)$ are not linear, they all have the same non-linear terms. Therefore, for $i \neq j$, we get that $h_i(x, r) = h_j(x, r)$ defines a *separating plane*

$$\gamma_{i,j} = \{(x, r) \in \mathbb{R}^3 : 2(a_i - a_j) \cdot x - 2(\kappa_i - \kappa_j)r = \|a_i\|^2 - \|a_j\|^2 - \kappa_i^2 + \kappa_j^2\}$$

As noted by Megiddo, this separating plane has the following property: If the solution (x, r) to our optimization problem is known to lie to one side of $\gamma_{i,j}$, then we know that one of the constraints is redundant.

In Megiddo's problem, it sufficed to have a *side-decision algorithm* to determine on which side of a plane $\gamma_{i,j}$ the solution lies. Megiddo showed how to implement such an algorithm in linear time on the number of constraints [10].

Using this side-decision algorithm, he shows how to solve the optimization problem. A variant of his technique could be described as follows: Start by pairing the functions arbitrarily, and then consider the set of separating planes defined by these pairs. For some constant r , compute a $1/r$ -cutting in \mathbb{R}^3 of the separating planes. An $1/r$ -cutting is a partition of the plane into $O(r^2)$ convex cells of constant size such that each intersects at most n/r separating planes. A cutting of planes can be computed in $O(n)$ time in \mathbb{R}^3 for any $r = O(1)$ [7]. After computing the cutting, determine in which of the cells the optimum lies by performing $O(1)$ calls to the side-decision algorithm. Because at least $(r - 1)n/r$ separating planes do not intersect this constant size cell, for each of them we can discard one of the constraints as it becomes redundant. Repeating this algorithm recursively we obtain a linear running time.

In this paper, we follow a similar approach, but our set of separating planes needs to be extended in order to handle apex functions as they are only partially defined. Note that each apexed triangle that intersects q^* has its endpoints either outside of q^* or on its boundary, i.e., each chord bounding an apexed triangle splits q^* into two convex regions.

7.1 Optimization problem in a convex domain

In this section we describe our algorithm to solve the optimization problem (P2). To this end, we start by pairing the apexed triangles arbitrarily to obtain $m/2$ pairs. By identifying the plane where P lies with the plane $Z_0 = \{(x, y, z) : z = 0\}$, we can embed each apexed triangle in \mathbb{R}^3 . A *plane-set* is a set consisting of at most five planes in \mathbb{R}^3 . For each pair (Δ_i, Δ_j) we define a plane-set as follows: For each chord bounding either Δ_i or Δ_j , consider the line extending this chord and the vertical extrusion of this line in \mathbb{R}^3 , i.e., the plane containing this chord orthogonal to Z_0 . Moreover, consider the separating plane $\gamma_{i,j}$. The set containing these planes is the plane-set of the pair (Δ_i, Δ_j) .

Let Γ be the union of all the plane-sets defined by the $m/2$ pairs of apexed triangles. Thus, Γ is a set that consists of $O(m)$ planes. Compute an $1/r$ -cutting of Γ in $O(m)$ time for some constant r to be specified later. Because r is constant, this $1/r$ -cutting splits the space into $O(1)$ convex cells, each bounded by a constant number of planes [7]. By using a side-decision algorithm (to be specified later), we can determine the cell Q of the cutting that contains the solution. Because Q is the cell of a $1/r$ -cutting of Γ , we know that at most $|\Gamma|/r$ planes of Γ intersect Q . In particular, at most $|\Gamma|/r$ plane-sets intersect Q and hence, at least $(r-1)|\Gamma|/r$ plane-sets do not intersect Q .

Let (Δ_i, Δ_j) be a pair such that its plane-set does not intersect Q . Let Q' be the projection of Q on the plane Z_0 . Because the plane-set of this pair does not intersect Q , we know that Q' intersects neither the boundary of Δ_i nor that of Δ_j . Two cases arise:

Case 1. If either Δ_i or Δ_j does not intersect Q' , then we know that their apex function is redundant and we can drop the constraint associated with this apexed triangle.

Case 2. If $Q' \subset \Delta_i \cap \Delta_j$, then we need to decide which constraint to drop. To this end, we consider the separating plane $\gamma_{i,j}$. Notice that inside the vertical extrusion of $\Delta_i \cap \Delta_j$ (and hence in Q), the plane $\gamma_{i,j}$ has the property that if we know its side containing the solution, then one of the constraints can be dropped. Since $\gamma_{i,j}$ does not intersect Q as $\gamma_{i,j}$ belongs to the plane-set of (Δ_i, Δ_j) , we can decide which side of $\gamma_{i,j}$ contains the optimum and drop one of the constraints.

Regardless of the case if the plane-set of a pair (Δ_i, Δ_j) does not intersect Q , then we can drop one of its constraints. Since at least $(r-1)|\Gamma|/r$ plane-sets do not intersect Q , we can drop at least $(r-1)|\Gamma|/r$ constraints. Because $|\Gamma| \geq m/2$ as each plane-set contains at least one plane, by choosing $r = 2$, we are able to drop at least $|\Gamma|/2 \geq m/4$ constraints. Consequently, after $O(m)$ time, we are able to drop $m/4$ apexed triangles. By repeating this process recursively, we end up with a constant size problem in which we can compute the upper envelope of the functions explicitly and find the minimum using exhaustive search. Thus, the running time of this algorithm is bounded by the recurrence $T(m) = T(3m/4) + O(m)$ which solves to $O(m)$. Because $m = O(n)$, we can find the solution to (P2) in $O(n)$ time.

The last detail is the implementation of the side-decision algorithm. Given a plane γ , we want to decide on which side lies the optimum of (P2). To this end, we solve (P2) restricted to γ , i.e., with the additional constraint of $(x, r) \in \gamma$. This approach was used by Megiddo [10], the idea is to recurse by reducing the dimension of the problem. Another approach is to find this using the algorithm described by Pollack et al. [11, Section 3].

Once the optimum of (P2) restricted to γ is known, we can follow the same approach used by Megiddo [10] to find the side of γ containing the global optimum. Intuitively, we find the apex functions that define the optimum restricted to γ . Since $\phi(x) = F_P(x)$ is locally defined by these functions, we can decide on which side the optimum lies using convexity. We obtain the following result.

► **Theorem 16.** Let q^* be a convex trapezoid contained in P such that q^* contains the geodesic center of P . Given the set of all apexed triangles of τ that intersect q^* , we can compute the geodesic center of P in $O(n)$ time.

► **Corollary 17.** Given a simple polygon P with n vertices, we can compute its geodesic center in $O(n \log^* n)$ time.
